# 35 1 Introduction

Talkers who share a common language vary in the way they pronounce its linguistic categories. Yet, listeners of the same language background typically cope with such variation without much 37 trouble. In scenarios where a talker produces those categories in an unexpected and unfamiliar way, comprehending their speech may pose a real challenge. However, brief exposure to the talker's accent (sometimes just minutes) can be sufficient for the listener to overcome any initial 40 comprehension difficulty (e.g. Bradlow & Bent, 2008; Clarke & Garrett, 2004; X. Xie, Liu, & Jaeger, 2021; X. Xie et al., 2018). This adaptive skill is in a sense, trivial for any expert language user but becomes complex when considered from the angle of acoustic-cue-to-linguistic-category 43 mappings. Since talkers differ in countless ways and each listening occasion is different in circumstance, there is not a single set of cues that can be definitively mapped to each linguistic category. Listeners instead have to contend with many possible cue-to-category mappings and infer the intended category of the talker. How listeners achieve prompt and accurate comprehension of speech in spite of this variability remains the overarching aim of speech perception research. 49

Researchers have been exploring the hypothesis that listeners solve this perceptual problem
by exploiting their knowledge gained from experience with different talkers. This knowledge is
often implicit and context contingent since listeners are sensitive to both social and environmental
cues (e.g. age, sex, group identity, native language etc.) that are relevant for optimal speech
perception. Impressively, shifts in perception can be induced implicitly through subtle cues such
as the presence of cultural artefacts that hint at talker provenance, (Hay & Drager, 2010) and
explicitly such as when the listener is instructed to imagine a talker as a man or a woman
(Johnson, Strand, & D'Imperio, 1999). While these and other related effects of exposure-induced
changes speak to the malleability of human perception, it remains unclear how human perceptual
systems strike the balance between stability and flexibility.

One possibility is that listeners continuously update their implicit knowledge with each
talker encounter by integrating prior knowledge of cue-to-category distributions with the statistics
of the current talker's productions, leading to changes in representations which can be observed in
listener categorisation behaviour. Broadly speaking, many theoretical accounts would agree with

this assertion. Connectionist (McClelland & Elman 1986; Luce & Pisoni, 1998), and Bayesian models of spoken word recognition (Norris & McQueen, 2008) and adaptation (D. F. 65 Kleinschmidt & Jaeger, 2015) are generative systems that abstract the frequency of input. Even exemplar models of speech perception (Goldinger 1996, 1998; Johnson, 1997; Pierrehumbert 2001) which encode high fidelity memories of speaker-specific phonetic detail converge to a level of generalisation due to effects of token frequency (Pierrehumbert2003?; DragerKirtley2016?). 69 At the level of acoustic-phonetic input, listeners' implicit knowledge refer to the way 70 relevant acoustic cues that distinguish phonological categories are distributed across talkers 71 within a linguistic system. Talkers of US-English, for instance, distinguish the /d/-/t/ contrasts primarily through the voice-onset-time (VOT) acoustic cue. Given its relevance for telling word 73 pairs such as "din" and "tin" apart, a distributional learning hypothesis would posit that listeners 74 learn the distribution of VOT cues when talkers produce those stop consonant contrasts in word 75 contexts. Earliest evidence for listener sensitivity to individual talker statistics in the domain of 76 stop consonants come from studies such as Allen & Miller (2004, also **TheodoreMiller2010?**) 77 but more recent studies that formalise the problem of speech perception as rational inference have shown that listeners' behavioural responses are probabilistic function of the exposure talker's statistics (Clayards, Tanenhaus, Aslin, & Jacobs, 2008; D. F. Kleinschmidt & Jaeger, 2016; and 80 Theodore & Monto, 2019). 81 Clayards et al. (2008) for instance found that listeners responded with greater uncertainty 82 after they were exposed to VOT distributions for a "beach-peach" contrast that had wider variances as compared to another group who had heard the same contrasts with narrower variances. Across both wide and narrow conditions, the mean values of the voiced and voiceless 85 categories were kept constant and set at values that were close to the expected means for /b/ and /p/ in US English. The study was one of the first to demonstrate that at least in the context of an experiment, listeners categorisation behaviour was a function of the variance of the exposure 88 talker's cue distributions – listeners who were exposed to a wide distribution of VOTs showed greater uncertainty in their perception of the stimuli, exhibiting a flatter categorisation function on average, compared to listeners who were exposed to a narrow distribution. 91

In a later study D. F. Kleinschmidt and Jaeger (2016) tested listener response to talker

92

statistics by shifting the means of the voiced and voiceless categories between conditions.

Specifically, the mean values for /b/ and /p/ were shifted rightwards by several magnitudes, as

well as leftwards, from the expected mean values of a typical American English talker while the

category variances remained identical and the distance between the category means were kept

constant. With this manipulation of means they were able to investigate how inclined listeners

are to adapt their categorisation behaviors when the statistics of the exposure talker were shifted

beyond the bounds of a typical talker.

In all exposure conditions, listeners on average adapted to the exposure talker by shifting their categorization function in the direction of the predicted function of an ideal listener (a listener who perfectly learned the exposure talker's cue statistics). However, in all conditions, listener categorization fell short of the predicted ideal categorization boundary. This difference between the observed and predicted categorization functions was larger, the greater the magnitude of the shift from the typical talker's distribution, suggesting some constraints on adaptation.

107

108

The study we report here builds on the pioneering work of Clayards et al. (2008) and D. F. Kleinschmidt and Jaeger (2016) with the aim to shed more light on the role of prior implicit knowledge on adaptation to an unfamiliar talker.

Specifically, while K&J16 demonstrated how prior beliefs of listeners can be inferred 109 computationally from post-exposure categorisation, their experiment was not designed to capture 110 listener categorisation data before exposure to a novel talker. Nor did they run intermittent tests 111 to scrutinise the progress of adaptation. In the ideal adapter framework, listener expectations are 112 predicted to be rationally updated through integration with the incoming speech input and thus 113 can theoretically be analysed on a trial-by-trial basis. The overall design of the studies reported 114 here were motivated by our aim to understand this incremental belief-updating process which has 115 not been closely studied in previous work. We thus address the limitations of previous work and 116 in conjunction, make use of ideal observer models to validate baseline assumptions that 117 accompany this kind of speech perception study – that listeners hold prior expectations or beliefs 118 about cue distributions based on previously experienced speech input (here taken to mean native 119 AE listeners' lifetime of experience with AE). Arriving at a definitive conclusion of what shape and form those beliefs take is beyond the scope of this study however we attempt to explore the 121

various proposals that have emerged from more than half a century of speech perception research.

A secondary aim was to begin to address possible concerns of ecological validity of prior 123 work. While no speech stimuli is ever ideal, previous work on which the current study is based did 124 have limitations in one or two aspects: the artificiality of the stimuli or the artificiality of the 125 distributions. For e.g. (Clayards et al., 2008) and (D. F. Kleinschmidt & Jaeger, 2016) made use 126 of synthesised stimuli that were robotic or did not sound human-like. The second way that those 127 studies were limited was that the exposure distributions of the linguistic categories had identical 128 variances (see also Theodore & Monto, 2019) unlike what is found in production data where the 129 variance of the voiceless categories are typically wider than that of the voiced category (Chodroff 130 & Wilson, 2017). We take modest steps to begin to improve the ecological validity of this study 131 while balancing the need for control through lab experiments by employing more natural sounding 132 stimuli as well as by setting the variances of our exposure distributions to better reflect empirical 133 data on production (see section x.xx. of SI). 134

# 2 Experiment 1: Listener's expectations prior to informative exposure

Experiment 1 investigates native (L1) US English listeners' categorization of word-initial stop voicing by an unfamiliar female L1 US English talker, prior to more informative exposure.

Specifically, listeners heard isolated recordings from a /d/-/t/ continuum, and had to respond which word they heard (e.g., "din" or "tin"). The recordings varied in voice onset time (VOT), the primary phonetic cue to word-initial stop voicing in L1 US English, as well as correlated secondary cues (f0 and rhyme duration). Critically, exposure was relatively uninformative about the talker's use of the phonetic cues in that all phonetic realizations occurred equally often. The design of Experiment 1 serves two goals.

The first goal is methodological. We use Experiment 1 to test basic assumptions about the paradigm and stimuli we employ in the remainder of this study. Experiment 1 provides perceptual norms for a new set of /d/-/t/ stimuli developed to improve ecological validity. While it is well-established that larger VOT values make it more likely that listeners categorize a

recording as having the voiceless stop (here "t"), the specific categorization function can vary between talkers (REFS?) and listeners (e.g., Clayards et al., 2008; D. F. Kleinschmidt & Jaeger, 150 2016). For Experiment 2, we wanted to have an estimate of the category boundary between /d/ 151 and /t/, as perceived by listeners of the type we seek to recruit for Experiment 2 and specifically 152 for the stimulus recordings we employ in all experiments. Categorization data from this first 153 experiment would also reveal differences in how listeners perceived the four minimal pairs if any. 154 Although we had no reason to expect them to elicit substantially different behaviour in 155 participants we did intend to use only three of the four pairs available, in experiment 2 in order to 156 be consistent with the previous studies that we wish to extend. In relation to establishing norms, 157 we also aimed to test whether listeners' categorization behavior changes over time even when 158 exposure is relatively uninformative—i.e., even when the stimuli listeners hear form a uniform 159 distribution across trials. If listeners exhibit changes in categorization behavior even for such 160 uninformative input, this would have implications for the interpretation of adaptive behavior 161 when input like the type we employ in Experiment 2 is actually informative . 162

The second purpose of Experiment 1 is to introduce and illustrate relevant theory. We 163 compare different models of listeners' prior expectations against listeners' categorization responses 164 in Experiment 1. The different models all aim to capture the implicit expectations of an L1 adult 165 listener of US English might have about the mapping from acoustic cues to /d/ and /t/ based on 166 previously experienced speech input. As we describe in more detail after the presentation of the 167 experiment, the models differ, however, in whether these prior expectations take into account that 168 talkers can differ in the way they realize /d/ and /t/. This ability to take into account talker 169 differences even prior to more informative exposure is predicted—though through qualitatively different mechanisms, as we discuss below—both by normalization accounts (Cole, Linebaugh, 171 Munson, & McMurray, 2010; McMurray & Jongman, 2011) and by accounts that attribute 172 adaptive speech perception to changes in category representations (Bayesian ideal adaptor theory, 173 D. F. Kleinschmidt & Jaeger, 2015; EARSHOT, Magnuson et al., 2020; episodic theory, 174 Goldinger, 1998; exemplar theory, Johnson, 1997; Pierrehumbert, 2001). It is, however, 175 unexpected under accounts that attribute adaptive speech perception solely to ad-hoc changes in 176 decision-making. We did not expect Experiment 1 to yield a decisive conclusion with regard to

this second goal, which is also addressed in Experiment 2. Rather, we use Experiment 1 as a presentationally convenient way to introduce some of the different models and provide readers with initial intuitions about what experiments of this type can and cannot achieve.

## 181 **2.1** Methods

182

191

#### 2.1.1 Participants

Participants were recruited over Amazon's Mechanical Turk platform, and paid \$2.50 each (for a 183 targeted remuneration of \$6/hour). The experiment was only visible to Mechanical Turk 184 participants who (1) had an IP address in the United States, (2) had an approval rating of 95% 185 based on at least 50 previous assignments, and (3) had not previously participated in any 186 experiment on stop voicing from our lab. 187 24 L1 US English listeners (female = 9; mean age = 36.2 years; SD age = 9.2 years) 188 completed the experiment. To be eligible, participants had to confirm that they (1) spent at least 189 the first 10 years of their life in the US speaking only English, (2) were in a quiet place, and (3) 190

wore in-ear or over-the-ears headphones that cost at least \$15.

#### 192 2.1.2 Materials

We recorded multiple tokens of four minimal word pairs ("dill"/"till", "dim"/"tim", "din"/"tin", and "dip"/"tip") from a 23-year-old, female L1 US English talker with a mid-Western accent.

These recordings were used to create four natural-sounding minimal pair VOT continua (dill-till, dip-tip, din-tin, and dip-tip) using a Praat script (Winn, 2020). The full procedure is described in the supplementary information (SI, ??). The VOT continua ranged from -100ms VOT to +130ms VOT in 5ms steps. Experiment 1 employs 24 of these steps (-100, -50, -10, 5 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, 65, 70, 75, 80, 85, 90, 100, 110, 120, 130).

We further set the F0 at vowel onset to follow the speaker's natural correlation which was
estimated through a linear regression analysis of all the recorded speech tokens. We did this so
that we could determine the approximate corresponding f0 values at each VOT value along the
continua as predicted by this talker's VOT. The duration of the vowel was set to follow the natural
trade-off relation with VOT reported in Allen and Miller (1999). This approach closely resembles

that taken in Theodore and Monto (2019), and resulted in continuum steps that sound highly
natural (unlike the robotic-sounding stimuli employed in Clayards et al., 2008; D. F. Kleinschmidt
Jaeger, 2016). All stimuli are available as part of the OSF repository for this article.

In addition to the critical minimal pairs we also recorded three words that did not did not contain any stop consonant sounds ("flare", "share", and "rare"). These word recordings were used as catch trials. Stimuli intensity were standardised at 70 dB sound pressure level.

## 211 **2.1.3 Procedure**

220

221

222

223

224

Participants underwent a headphones test and gave their consent to the study following the 212 guidelines of the Research Subjects Review Board of the University of Rochester. After 213 participants passed the headphones test and gave their consent they were taken to an instructions 214 page. They were informed that they would hear a female talker say a word and that they would 215 have to select which word they heard. They were instructed to listen carefully and answer as 216 quickly and as accurately as possible. They were also alerted to the fact that the recordings were 217 subtly different and therefore may sound repetitive. This was done to encourage their full 218 attention to the playbacks. 219

Each trial started with a green fixation dot being displayed. At 500ms from trial onset, two minimal pair words appeared on the screen, as shown in Figure 1. At 1000ms from trial onset, an audio recording from the matching minimal pair continuum started playing. Participants were required to click on the word they heard. After participants clicked on the word, the next trial began.

The trials were presented randomly and the order of the written word forms were 225 counter-balanced across participants. Participants were given 192 target trials along a 24-step 226 VOT continuum to categorise. VOT tokens in the lower and upper ends were distributed over 227 larger increments because stimuli in those ranges were expected to elicit floor and ceiling effects, 228 respectively. Each word pair was played twice at each VOT step, constituting a uniform 229 distribution. In addition to the critical trials, 12 catch trials were inserted randomly throughout 230 the experiment. These trials served as a check on participant attention throughout the 231 experiment. Participants were given the opportunity to take breaks after every 60 trials. 232

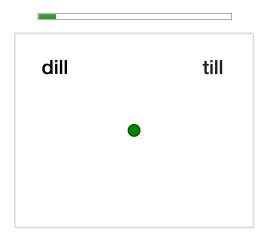

Figure 1. Example trial display. The words were displayed 500ms after trial onset and the audio recording of the word was played 1000ms after trial onset

Participants spent an average of 12 minutes (SD = 4.8) on the trials after which they answered a short survey about the experiment.

#### 235 2.2 Results

We first present the behavioral analyses of listeners' categorisation responses, and then compare them to predictions of ideal observers.

#### 238 2.2.1 Exclusions

We excluded from analysis participants who committed more than 3 errors out of the 12 catch trials (<75% accuracy, N = 3), participants with an average reaction time (RT) more than three standard deviations from the mean of the by-participant means (N = 0), and participants who reported not to have used headphones (N = 0) or not to be native (L1) speakers of US English (N = 0). For the remaining participants, trials that were more than three SDs from the participant's mean RT were excluded from analysis (1.6%). Finally, we excluded participants (N = 0) who had less than 50% data remaining after these exclusions.

## 6 2.2.2 Behavioral analyses

The goal of our behavioral analyses was to address three methodological questions that are of relevance to Experiment 2: (1) whether our stimuli resulted in 'reasonable' categorisation

functions, (2) whether these functions differed between the four minimal pair items, and (3) whether participants' categorisation functions changed throughout the 192 test trials.

To address these questions, we fit a single Bayesian mixed-effects psychometric model to 251 participants' categorization responses on critical trials (e.g., prins2011?). The model describes 252 the probability of "t"-responses as a weighted mixture of a lapsing-model and a perceptual model. 253 The lapsing model is a mixed-effects logistic regression (Jaeger, 2008) that predicts participant responses that are made independent of the stimulus—for example, responses that result from 255 attentional lapses. These responses are independent of the stimulus, and depend only on 256 participants' response bias. The perceptual model is a mixed-effects logistic regression that 257 predicts all other responses, and captures stimulus-dependent aspects of participants' responses. 258 The relative weight of the two models is determined by the lapse rate, which is described by a 250 third mixed-effects logistic regression. 260

The lapsing model only had an intercept (the response bias in log-odds) and by-participant 261 random intercepts. Similarly, the model for the lapse rate only had an intercept (the lapse rate) 262 and by-participants random intercepts. Previous studies with similar paradigms have typically 263 found lapse rates of 0-10% (< -2.2 log-odds, e.g., Clayards et al., 2008; D. F. Kleinschmidt & 264 Jaeger, 2016). No by-item random effects were included for the lapse rate nor lapsing model since these parts of the analysis—by definition—describe stimulus-independent behavior. The 266 perceptual model included an intercept and VOT, as well as the full random effect structure by 267 participants and items (the four minimal pair continua), including random intercepts and random 268 slopes by participant and minimal pair. We did not model the random effects of trial to reduce 269 model complexity. This however makes our analysis of trials in the model anti-conservative. 270

Based on previous experiments, we expected a strong positive effect of VOT, with
increasing proportions of "t"-responses for increasing VOTs. We did not have clear expectations
for the effect of trial other than that responses should become more uniformed (i.e move towards
50-50 "d"/"t"-bias or 0-log-odds) as the experiment progressed (Liu & Jaeger, 2018a) due to the
un-informativeness of the stimuli. Finally, the models included the covariance between
by-participant random effects across the three linear predictors for the lapsing model, lapse rate
model, and perceptual model. This allows us to capture whether participants who lapse more
